Introduction

Studies that employed autopsy as a criterion standard have found that pulmonary embolism (PE) follows acute coronary syndrome as the second most common cause of sudden unexpected death in outpatients [1-3]. PE manifests in a broad clinical spectrum of severity, ranging from vague chest discomfort with normal vital signs to sudden death [4-6]. At least one-quarter of outpatients diagnosed with PE have no overt risk factors [7,8]. Experts often suggest that physicians continue to miss the diagnosis of PE at an unacceptably high rate, and patients with a delayed diagnosis of PE have worsened outcomes [9,10]. Coincidentally, several reports have indicated that physicians hold an increasing perception of risk of medical malpractice secondary to failure to order a diagnostic test for PE [11,12]. These influences, together with the widened availability and acceptance of the D-dimer and computed tomography (CT) angiography as diagnostic tests for PE, may have combined to cause an increase in the frequency of testing for PE among very low risk outpatients [13]. Speculative investigation for PE that leads to large numbers of negative CT angiograms in young patients may have negative consequences in the form of increased risk of malignancy secondary to radiation exposure [14,15].

In 2004, we derived the pulmonary embolism rule-out criteria (PERC), an eight-factor decision rule to support the decision not to order a diagnostic test for PE in patients for whom the clinician already had a low clinical suspicion for PE.
based on a gestalt impression [16]. The PERC criteria negative
[PERC(−)] requires the clinician to answer ‘no’ to the following
eight questions:
1. Is the patient older than 49 years of age?
2. Is the pulse rate above 99 beats min⁻¹?
3. Is the pulse oximetry reading < 95% while the patient
breathes room air?
4. Is there a present history of hemothysis?
5. Is the patient taking exogenous estrogen?
6. Does the patient have a prior diagnosis of venous throm-
boembolism (VTE)?
7. Has the patient had recent surgery or trauma? (Requiring
endotracheal intubation or hospitalization in the previous
4 weeks.)
8. Does the patient have unilateral leg swelling? (Visual
observation of asymmetry of the calves.)

We use the term very low risk to describe patients with
the combination of both gestalt low suspicion and PERC(−). Each
patient in the very low risk group should have a pretest
probability of less than the test threshold for PE. The test
threshold represents a numeric estimate of the pretest proba-
bility, which defines a point of equipoise: patients with a pretest
probability lower than the test threshold should not benefit
(and may even be harmed) from diagnostic testing. Using the
method of Pauker and Kassirer, we have previously estimated
the point of equipoise to be 2% (rounded to the nearest whole
per cent) [16,17]. The ultimate goal is to produce an actual
outcome frequency (i.e. a posterior probability) of VTE that is
below 1%, as has been suggested to be a goal of a PE rule-out
protocol [18]. We hypothesized that patients undergoing
evaluation for possible PE, but who satisfied our definition of
very low risk, would have a measured 45-day incidence of
VTE(+) or death with an upper-limit 95% confidence interval
(95% CI) below 2.0%.

Methods
This was a prospective, non-interventional, multicenter study
of patients presenting to the emergency department (ED) in 12
hospitals in the USA and one in Christchurch, New Zealand.
Prior to the study initiation, a project manager traveled to each
site (except New Zealand) in order to train site investigators
and research associates on protocol methodology. This indi-
vidual was then available full-time by telephone and e-mail,
and, if needed, for face-to-face visits throughout the study
duration as a resource to investigators. The study protocol was
approved by the Institutional Review Boards for the conduct of
research on humans and the Privacy Boards of all 13 hospitals.
Patients were enrolled from July 1, 2003 until November 30,
2006. The event that triggered eligibility for enrollment was an
order for an objective diagnostic test for PE, written by or
under the supervision of a board-certified emergency physician.
The decision to order this test was based upon information
obtained from the initial history and physical examination,
and medical records immediately available in the ED. We defined
objective diagnostic testing for PE as either a pulmonary
vascular imaging study [CT angiography or scintillation
ventilation-perfusion (VQ) lung scanning] or a D-dimer assay
ordered to evaluate for possible PE. Tests performed for
suspected DVT only did not trigger enrollment. Pre-enrollment
exclusions were as follows. (i) Clinician's knowledge of a
diagnostic positive pulmonary vascular imaging study per-
formed within the previous 7 days. (ii) The patient indicated
that the enrollment hospital was not his or her hospital system
of choice for follow-up. (iii) Any circumstance that suggested
that the patient would be lost to follow-up (e.g. homeless
patients, patients with severe psychiatric disorders, patients
who could not provide a reliable telephone number, interna-
tional travelers, inmates in State or Federal penitentiaries,
persons arrested for felonies). These exclusions were deter-
mined in the ED by qualified study personnel.

Sites had the option of enrolling patients in one of two ways:
either by using randomly selected 8-h time blocks or by using
all patients consecutively with a defined target rate of > 85%.
Adherence to the 85% threshold was estimated by a retro-
spective review of computerized order-entry databases (see
Appendix), which was used to locate and total the number of
D-dimer studies ordered for adults with one or more of the
symptoms shown in Table 1 (or obvious documentation of PE
suspicion), all VQ scans and all CT pulmonary angiography
studies ordered and carried out during the active hours of
enrollment. These reviews were performed on a quarterly basis.
A patient could be enrolled more than once if he or she had a
test ordered for PE on separate days of presentation. Enroll-
ment was completed after 500 patients or 18 months of data
collection. If a site could not achieve > 85% capture with
consecutive enrollment, this triggered a medical record review
of patients who were eligible for enrollment but who were
missed (i.e. the intent-to-study group). The purpose of this
intent-to-study group was to allow statistical comparison of the
key demographics and frequency of VTE between enrolled vs.
missed patients [19]. If the number of missed patients exceeded
the number enrolled, then data were abstracted from a random
sample of missed patients equal to the number enrolled. Data
abstraction was performed using published methods [20].

A key technical objective was to collect clinical data
(including the gestalt estimate of clinical suspicion) that
accurately represented the clinicians' beliefs at the time when
he or she decided to order a diagnostic test for PE, but prior to
knowing the results. In order to achieve this objective, clinicians
collected and recorded study data coincident with clinical care,
as illustrated in Figure 1. Data were entered into a web-based,
secure, electronic data collection form. This protocol specified
that the form be completed before the results of testing were
known, and the form required the clinician to input if he or she
had knowledge of any test results pertinent to diagnosis of VTE
at the time it was populated. A full description of the content
and methodology for this data collection system has been
published [21]. Physicians clicked one of three radio buttons
to encode gestalt pretest probability estimates for PE as < 15%,
15−40% or > 40%. The form then asked for the data required
for the PERC rule as well as 65 other data points. All fields had

Clinical step

- Clinician evaluated patient in ED
- Decision made to order diagnostic test for PE
- Tests ordered, care continues
- Diagnostic test results
  - Discharged
  - Admitted
- Follow-up data gathered via
  - Follow-up data form completed
- Follow-up web-based data form populated in ED
- Outcome at 45 days

Research step

- Screened for inclusion and exclusion criteria
- Prospective data gathered and web-based data form populated in ED
- Medical record review and telephone calls

Fig. 1. Overview of research-related activities, relative to the main steps in clinical care. ED, emergency department; PE, pulmonary embolism.

Form. Once the data form was uploaded, the patient was enrolled, and no patients were excluded. To help to ensure comprehensive follow-up, we recorded if the patient stated that the enrollment hospital was his or her preferred hospital. Figure 2 shows the suggested diagnostic algorithm to allow exclusion of PE in the ED that was provided to all clinicians who participated. Imaging protocols were overseen by the radiology department at each institution and all image results were from the final interpretations signed by a board-certified radiologist.

We followed all enrolled patients for outcome at 45 days. We have found that a longer time interval reduces the probability of successful contact [20]. No patients were excluded on the basis of follow-up. The protocol required one of the following: documented follow-up history and a physical examination that contained sufficient information to allow the site investigator to determine the VTE status at 45 days, or telephone or mail contact with the patient, or a family member, or the patient's clinician. If we were unable to obtain a medical record, and could not contact the patient, we searched the social security death index to determine vital status (http://ssdi.rootsweb.com). We obtained a death certificate for all decedents. We documented the results of

Fig. 2. Overview of the diagnostic algorithm used by all 13 study hospitals to exclude the diagnosis of pulmonary embolism (PE) in the emergency department. All patients had either D-dimer, computed tomography (CT) angiography or ventilation-perfusion (VQ) lung scan performed. Solid lines depict primary pathways and dotted lines represent secondary pathways. *Yale University used a qualitative D-dimer.

tests, clinical diagnoses, treatments, death-related data, and findings from telephone interviews on a more extensive, web-based follow-up form that encoded 143 data fields [21]. Consistent with contemporaneous research and expert opinion [22-25], we used either PE or deep venous thrombosis (DVT) as evidence of VTE(+) in the reference standard. The VTE status was established by an adjudicated review of imaging results, medical records, and follow-up. The assignment of present or absent VTE within 45 days required agreement between two independent clinicians who used explicit criteria. Positive evidence of PE required either a high-probability VQ scan or a CT angiogram or conventional pulmonary angiogram that demonstrated a pulmonary arterial filling defect interpreted as positive for acute PE, or an autopsy positive for PE. Positive evidence of DVT required extremity venous duplex Doppler-ultrasonography or CT venography interpreted as positive for acute venous thrombosis in the popliteal, femoral or axillary (but not calf) veins. Diagnosis of VTE also required written documentation of a clinical plan to treat with anticoagulation using either a vitamin K antagonist, or parenteral low-molecular-weight heparin for ≥3 months, or insertion of a vena cava filtering device in a patient with a contraindication to anticoagulation. Exclusion of VTE required the absence of positive imaging for VTE and no treatment for VTE within 45 days. For the intent-to-study group (eligible patients not enrolled during the time of active enrollment and not included in the main analysis), the diagnosis of VTE(+) required one or more VTE-related ICD-9 (or -10) codes (415.X, 451.X and 453.X) to be documented within 45 days of having a diagnostic test ordered to rule out PE in the ED while the study was actively enrolling.

**Statistical analysis**

The hypothesis stated that the upper limit of the 95% CI for the proportion of very low risk patients who met the primary endpoints of VTE(+) or death from any cause within 45 days would not exceed 2.0%. For the sample size calculation, we estimated that approximately 20% of the cohort patients would fall into the very low risk category and that 1% of these patients would actually have the primary endpoint of VTE diagnosed within 45 days. Using the method described by Arkin, we computed that a sample size of 7000 patients would allow us reject the null hypothesis at α = 0.05 (i.e. <5% probability that the true incidence of VTE was >2.0% in very low risk patients) and to demonstrate an 80% power to narrow one side of the 95% CI to <1.0% [26]. We used the Clopper–Pearson exact method to compute confidence intervals for proportions (StatsDirect version 2.4.4, Cheshire, UK).

**Results**

The study enrolled 8138 patients from 12 213 eligible patients. Figure 3 shows the outcomes of all patients. Table 1 describes the demographic data, age and clinical characteristics of the cohort. The mean age was 49 years, and women comprised approximately two-thirds of the cohort. The first symptom that prompted the ED visit was chest pain (53%), dyspnea (33%), cough (3%), syncope (2%), respiratory distress (2%), seizure (0.1%) and other (7%). Fifty-five per cent of patients indicated that their first symptom onset was 'sudden' and 45% said the onset was 'gradual'. Seventy-six per cent of the cohort had one or more of the comorbid conditions listed in Table 1. Forty-two
per cent had either a respiratory rate > 22 breaths min\(^{-1}\) or a pulse rate > 100 beats min\(^{-1}\) at the time of enrollment.

Table 2 summarizes the associated beliefs and actions of clinicians that are pertinent to assessing their clinical suspicion for PE. Clinicians documented a low clinical suspicion (i.e. gestalt impression <15\%) in two-thirds of all patients, and 80\% of clinicians recorded that they believed an alternative diagnosis was more likely than PE at the time they ordered a diagnostic test for PE.

Table 3 shows the results of diagnostic testing for PE. Seventy-four per cent of patients had a D-dimer ordered; 55\% had CT angiography, VQ scanning, or both performed. In 5999 (74\%) patients, the results of PE-related diagnostic tests were completely normal.

Table 4 shows the outcomes that occurred within 45 days of enrollment. Of 8138 patients tested for possible PE in the ED, a total of 513 were diagnosed with VTE during the index visit. Follow-up found that 47 patients (0.5\% of the cohort) were diagnosed with VTE after discharge from the index visit but were not diagnosed at the time of the index ED visit or hospitalization. One patient died of undiagnosed PE discovered at autopsy. Thus, 561 patients (6.9\%) met a criterion standard for the diagnosis of VTE(+) within 45 days. The median 45 day incidence of VTE(+) among the 13 sites was 6.9\% (interquartile range 5.8–8.6\%). The measured 45-day incidences of VTE(+) stratified by the gestalt pretest probability estimates of <15\%, 15–40\% and >40\% were 3.0\%, 10.4\% and 31.1\%, respectively.

*Pulmonary embolism (PE) and deep vein thrombosis (DVT) required imaging evidence and a clinical plan to treat within 45 days of enrollment. VTE, venous thromboembolism.

Four sites (Northwestern Memorial, Pitt County Memorial, St. Vincent Mercy Medical and William Beaumont) enrolled consecutively but did not meet the prespecified 85% goal, and were thus considered as convenience samples. We therefore performed a medical record review of a random sample of missed patients, equal to the number enrolled at each of these four sites (n = 2040), and compared the demographics of these patients with those of the 8138 patients that we enrolled. The mean age of these 2040 patients was 52 ± 18.7 years, 64% were female, 55% were Caucasian, and 130 (6.4%) were diagnosed with VTE(+), including 3.9% with PE only, 1.1% with DVT only, and 1.3% with both PE and DVT. The 95% CI for the 0.5% difference between this 6.4% vs. the 6.9% in the study cohort was −1.7 to 0.7%, suggesting no significant difference in the VTE(+) rate between the study cohort and the intent-to-study group.

95% CI, 95% confidence interval; PE, pulmonary embolism; PERC, pulmonary embolism rule-out criteria; very low risk, no test needed; VTE, venous thromboembolism.

*Age < 50 years, pulse < 100 beats min⁻¹, SaO₂ ≥ 95%, no hemoptysis, estrogen use, surgery/trauma requiring hospitalization within 4 weeks, or prior VTE, and no unilateral leg swelling.

Table 5 shows the outcomes of patients based upon the results of the PERC rule. Clinicians recorded all eight variables of the PERC rule as negative in 1952 (24%) patients. The false-negative rate in this subgroup was 1.2% (95% CI 0.8-1.8%) for VTE(+) and the false-negative rate was 1.3% (95% CI 0.8-1.9%) for the combined endpoints of either VTE(+) or death from any cause within 45 days. If we were to treat PERC(−) as an independent diagnostic test, its sensitivity would have been 95.7% (95% CI 93.6-97.2%), the specificity would equal 25.4% (95% CI 24.4-26.4%), and the negative likelihood ratio would have been 0.17 (95% CI 0.11-0.25%).

Sixteen hundred and sixty-six patients (20% of the cohort) were classified as very low risk. On a per-site basis, the proportion of patients in this very low risk group ranged from 10% to 36%, with a median value of 19% for all 13 sites. The false-negative rate in this very low risk subgroup was 0.9% (95% CI 0.5-1.3%) for VTE(+) and 1.0% (0.6-1.6%) for VTE(+) or death from any cause within 45 days. If it were treated as a diagnostic test, the very low risk classification would have yielded a diagnostic sensitivity equal to 97.4% (95% CI 95.8-98.5%), a specificity equal to 21.9% (95% CI 21.0-22.9%), and a negative likelihood ratio equal to 0.12 (95% CI 0.07-0.19%).

Additionally, 1745 patients were classified by clinicians as having both an alternative diagnosis more likely than PE, and PERC(−), and 16 of these were VTE(+) within 45 days, yielding a posterior probability of 0.9% (95% CI: 0.5-1.5%).

Discussion

In this large, multicenter study, we found that clinicians employ a very low threshold to test for PE, resulting in a very high rate of negative testing and a low rate of PE diagnosis. We used rigorous methodology to ensure a patient sample and a dataset that would allow broad inferences about the perceptions of clinicians when they tested for PE. To our knowledge, this is the largest prospective study of patients tested for PE. We enrolled patients from urban and rural settings, from teaching and community hospitals, and at high altitudes. We recognized the potential roles of convenience sampling and the informed consent process as sources of bias, and we attempted to control for these by our sampling methods and by cross-checking.
patients who were eligible but were missed for enrollment [27].

The study population was diverse in racial and ethnic composition and the patients were drawn from a wide geographic range.

We found that in two-thirds of cases, emergency clinicians harbored a low suspicion for PE when they ordered a diagnostic test to evaluate for PE. In 80% of cases, clinicians ordered a diagnostic test for PE with the belief that an alternative diagnosis was more likely. Eighteen hundred and forty-three patients underwent a CT angiography that yielded images interpreted as completely normal by a board-certified radiologist. While we recorded the category of 'other' interpretations in 36% of CT angiograms, the majority of these were of questionable significance (e.g. enlarged lymph nodes or small pleural effusion). Taken together, the combination of low physician pretest suspicion and the preponderance of negative imaging results infer the opportunity for the PERC rule to save resources and time, and to reduce patient exposure to the potential negative impact of ionizing radiation and iodinated contrast [14, 15, 28, 29]. Of relevance, the very low risk subgroup included 362 patients who had a completely normal CT angiography.

The clinician’s clinical suspicion for PE was low and the PERC rule was negative in 1666 patients, or 20% of the cohort. In this very low risk subgroup, 1.0% were VTE(+) or died within 45 days, and the top limit 95% CI of this proportion was 1.6%. Similarly, the clinician indicated that an alternative diagnosis was more likely than PE and the PERC rule was negative in 1745 patients, and only 16/1745 (0.9%, 95% CI 0.5–1.5%) had VTE within 45 days. Thus, the very low risk categorization produced a false-negative rate similar to that observed after a negative quantitative D-dimer, a normal scintillation lung scan, a negative multidetector CT chest angiography, or formal pulmonary angiography negative for PE [30, 31]. Only one very low risk patient died (of end-stage cancer) within 45 days.

Three published studies have performed secondary analyses of existing databases to test the performance of the PERC rule, independently of gestalt reasoning [32–34]. In aggregate, these studies included 1542 patients, of whom 362 (24%) were PERC(–) and nine (2.4%) were VTE(+) [35, 36]. Regardless of its level of validation, we submit that most clinicians currently employ gestalt reasoning as their primary method of formulating pretest probability [37].

Limitations of our study could include the requirement for gestalt interpretation of low risk. Moreover, this was not a management study; clinicians did not use the PERC rule instead of diagnostic testing in any patient, therefore the true safety of the PERC rule cannot be fully inferred. Some may hesitate to use clinical criteria that are not 100% sensitive in order to exclude a potentially fatal disease. It could be speculated that patients in our cohort differed from ED patients in other countries. We found that only 5.9% of our cohort had PE within 45 days, and 6.9% had either PE or DVT within 45 days. The classification of VTE status by adjudicators also was dependent upon the judgment of their physicians. It should be emphasized that the underlying prevalence of VTE may be too high in other ED populations for this strategy to be able to safely rule out PE [23, 38, 39]. Thus, we would suggest that prior to implementation at any hospital, the tandem strategy of using gestalt <15% and PERC(–) should be pilot-tested in an observational quality assurance study, in order to ensure an acceptably low posterior probability (e.g. <1%) [18].

In summary, we followed a cohort of 8138 outpatients who were tested for PE in the ED, and found that 6.9% were VTE(+) within 45 days. One-fifth of the cohort could have been classified as very low risk, defined as a gestalt pretest probability <15% and PERC(–). In this very low risk subgroup, 1.0% (95% CI 0.6–1.6%) had VTE within 45 days. The combination of a clinician’s gestalt estimate of a pretest probability of less than 15% and PERC(–) selects a subgroup of patients with a very low probability of VTE.
